# Improved Approximating Algorithms for Directed Steiner Forest 

Moran Feldman* Guy Kortsarz ${ }^{\dagger} \quad$ Zeev Nutov ${ }^{\ddagger}$

#### Abstract

We consider the $k$-Directed Steiner Forest ( $k$-DSF) problem: Given a directed graph $G=(V, E)$ with edge costs, a collection $\mathcal{D} \subseteq V \times V$ of ordered node pairs, and an integer $k \leq|D|$, find a minimum cost subgraph $H$ of $G$ that contains an $s t$-path for (at least) $k$ pairs $(s, t) \in \mathcal{D}$. When $k=|\mathcal{D}|$, we get the Directed Steiner Forest (DSF) problem. The best known approximation ratios for these problems are: $\tilde{O}\left(k^{2 / 3}\right)$ for $k$-DSF by Charikar et al. [2], and $O\left(k^{1 / 2+\varepsilon}\right)$ for DSF by Chekuri et al. [3]. We improve these approximation ratios as follows.

For DSF we give an $O\left(n^{\varepsilon} \cdot \min \left\{n^{4 / 5}, m^{2 / 3}\right\}\right)$-approximation scheme using a novel LP-relaxation that seeks to connect pairs with "cheap" paths. This is the first sub-linear (in terms of $n=|V|$ ) approximation ratio for the problem; all previous algorithm had ratio $\Omega\left(n^{1+\varepsilon}\right)$.

For $k$-DSF we give a simple greedy $O\left(k^{1 / 2+\varepsilon}\right)$-approximation algorithm. This improves upon the best known ratio $\tilde{O}\left(k^{2 / 3}\right)$ by Charikar et al. [2], and (almost) matches, in terms of $k$, the best ratio known for the undirected variant [14]. Even when used for the particular case of DSF, our algorithm favorably compares to the one of [3], which repeatedly solves linear programs and uses complex space and time consuming transformations. Our algorithm is much simpler and faster, since it essentially reduces $k$-DSF to a variant of the Directed Steiner Tree problem. The simplification is due to a new notion of "junction star-tree" - a union of an in-star and an out-branching having the same root, which is of independent interest.

[^0]
## 1 Introduction

Network design problems seek to find a minimum cost subgraph of a given (directed or undirected) graph, that satisfies some prescribed properties, often connectivity requirements. These problems are among the most studied problems in the fields of Combinatorial Optimization and Approximation Algorithms. We hereby list some classic network design problems on undirected graphs. One of the most basic network design problems is the Steiner Tree problem: given a graph $G=(V, E)$ with edge costs, and a set $T \subseteq V$ of terminals, find a minimum cost subtree of $G$ that spans $T$. This classic NP-hard problem was extensively studied with respect to approximation (see [32] and the references therein). A classic generalization is the Steiner Forest problem: Given a graph $G=(V, E)$ with edge costs and a collection $D \subseteq V \times V$ of (unordered) node pairs, find a minimum cost subgraph $H$ of $G$ that connects all pairs in $\mathcal{D}$ (namely, contains an st-path for every $\{s, t\} \in \mathcal{D}$ ). The best approximation ratio known for Steiner Forest is 2 [1] (see also [13] for a more general algorithm and a simpler proof). In the more general $k$-Steiner Forest problem, we are also given an integer $k \leq|\mathcal{D}|$, and the goal is to connect at least $k$ (arbitrary) pairs from $D$. Here a significant obstacle lies in the way of achieving a good (e.g. polylogarithmic) approximation ratio, even for undirected graphs. It was observed in [15] that $k$-Steiner Forest is harder than the Densest $k$-Subgraph problem, which is commonly believed not to admit a polylogarithmic approximation. See [9] for an $O\left(n^{1 / 3-\delta}\right)$ approximation algorithm for Densest $k$-Subgraph, with $\delta \approx 1 / 60$. Despite several attempts, this ratio was not improved for 11 years. The best known approximation ratio for $k$-Steiner Forest is $O(\min \{\sqrt{n}, \sqrt{k}\})$, see a recent paper by Gupta et al. [14]. In [14] the $k$-Steiner Forest problem is shown to have further significance due to its relation to the Dial a Ride problem.

In this paper we consider the directed variant of the $k$-Steiner Forest problem, namely:

## $k$-Directed Steiner Forest ( $k$-DSF)

Instance: A directed graph $G=(V, E)$, edge costs $\{c(e): e \in E\}$, a set $\mathcal{D} \subseteq V \times V$ of ordered pairs, and an integer $k \leq|\mathcal{D}|$.
Objective: Find a min-cost subgraph $H$ of $G$ that contains an st-path for (at least) $k$ pairs $(s, t) \in \mathcal{D}$.
When $k=|\mathcal{D}|$ we get the Directed Steiner Forest (DSF) problem. Another particular case of $k$-DSF is the $k$-Directed Steiner Tree ( $k$-DST) problem, where $\mathcal{D}=\{s\} \times T$ for some $s \in V$ and a terminal set $T \subseteq V-\{s\}$.
Remark: The name "Directed Steiner Forest" is used to relate the problem to the undirected version. In the undirected version, any minimal feasible solution is a forest, but in the directed case, the structure of a solution may be more complicate (e.g., it may contain cycles). For example, if all costs are 1 and $\mathcal{D}=V \times V$, then a directed Hamiltonian cycle is the best solution one can expect.

### 1.1 Directed and undirected Steiner problems

Usually, directed variants of network design problems are much harder to approximate than the undirected ones (we shall later see that for $k$-DSF this is not the case). For example, while the undirected Steiner Tree and the $k$-Steiner Tree problems both admit a constant approximation ratio (see [33, 11]), even a very special case of DST - the Group Steiner Tree problem on trees, is unlikely to admit a $\log ^{2-\varepsilon} n$ ratio for any $\varepsilon>0[16]$. In fact, the best known ratio for DST is much worse than its proved
lower bound. Extending and simplifying the recursive greedy method introduced by Zelikovsky [35] and Kortsarz and Peleg [26], Charikar et al. [2] gave a combinatorial $O\left(\ell^{3} k^{2 / \ell}\right)$-approximation algorithm for $k$-DST that runs in $O\left(k^{2 \ell} n^{\ell}\right.$ ) time (where $k=|T|$ ). Substituting $\ell=2 / \varepsilon$ gives an $O\left(k^{\varepsilon}\right)$-approximation scheme, namely, an $O\left(k^{\varepsilon} / \varepsilon^{3}\right)$-approximation algorithm that runs in $O\left(k^{4 / \varepsilon} n^{2 / \varepsilon}\right)$ time for any fixed $\varepsilon>0$. Substituting $\ell=\log k$ gives an $O\left(\log ^{3} k\right)$-approximation in quasi-polynomial time.

For the Steiner Forest problem, the gap between the directed and undirected variants is even wider. The problem admits a constant approximation for undirected graphs [1, 13]. However, for DSF strong lower bounds are known [7]. Dodis and Khanna [7] showed that DSF is at least as hard as the LABELCOVER max problem [31]. This implies that DSF cannot be approximated within $O\left(2^{\log ^{1-\varepsilon} n}\right)$ for any fixed $\varepsilon>0$, unless NP-hard problems can be solved in quasi-polynomial time [31].

The situation for DSF (and thus also for the more general $k$-DSF) is much worse than the above in the current state of the art. The best known ratio for LABEL-COVER $\max$ is $O(\sqrt{n})$ [30]. This ratio seems hard to improve and a better ratio for LABEL-COVER $\max$ is not known even for very simple versions of the problem (e.g., when the structure of the graph obeys the rules of the Unique Game Conjecture [20], when the admissible pairs of answers of the two provers on any fixed query induces a matching). If LABEL-COVER $\max$ is indeed $\Omega(\sqrt{n})$ hard to approximate, then so is DSF. Still, there is no evidence yet discarding the possibility that DSF admits an $O(\sqrt{n})$ approximation ratio.

Perhaps the most extreme example of the difference between undirected and directed network design problems is the Steiner Network problem. In this problem each pair $(s, t) \in \mathcal{D}$ has a connectivity requirement $r(s, t)$, namely, $r(s, t)$ edge disjoint $s t$-paths are required for every $(s, t) \in \mathcal{D}$. On undirected graphs, this problem admits a 2-approximation algorithm due to Jain [19]. As far as we know no non-trivial ratio is known for the Steiner Network problem on directed graphs.

Table 1 summarizes the best known approximation ratios for Steiner Network problems, prior to our work. For other related problems, including the closely related Group Steiner Tree problem see $[4,12,22,16,18,10,25]$ and surveys in [8] and [21, 24].

| Problem | Undirected |  | Directed |  |
| :--- | :---: | :---: | :---: | :---: |
|  | In terms of $n$ | In terms of $k$ | In terms of $n$ | In terms of $k$ |
| Steiner Tree | $1.55[33]$ | $1.55[33]$ | $O\left(n^{\varepsilon}\right)[2]$ | $O\left(k^{\varepsilon}\right)[2]$ |
| $k$-Steiner Tree | $2[11]$ | $2[11]$ | $O\left(n^{\varepsilon}\right)[2]$ | $O\left(k^{\varepsilon}\right)[2]$ |
| Steiner Forest | $2[1]$ | $2[1]$ | $O\left(n^{1+\varepsilon}\right)$ | $O\left(k^{1 / 2+\varepsilon}\right)[3]$ |
| $k$-Steiner Forest | $O(\sqrt{n})[14]$ | $O(\sqrt{k})[14]$ | $\tilde{O}\left(n^{4 / 3}\right)[2]$ | $\tilde{O}\left(k^{2 / 3}\right)[2]$ |
| Steiner Network | $2[19]$ | $2[19]$ | $n^{2}$ | $k$ |

Table 1: Best known approximation ratios for Steiner Network problems, prior to our work. We improve the ratio in terms of $n$ for Steiner Forest on directed graphs, and both ratios in terms of $n$ and $k$ for $k$-Steiner Forest, again, on directed graphs.

### 1.2 Our results

For DSF, the best known approximation ratio, in terms of $n$, is $O\left(n^{1+\varepsilon}\right)$, which can be easily derived from the algorithm of [2] for DST. For $k$-DSF, Charikar et al. [2] gave an $\tilde{O}\left(k^{2 / 3}\right)$-approximation algorithm, which in terms of $n$ can be as bad as $\tilde{O}\left(n^{4 / 3}\right)$, if $k=\Theta\left(n^{2}\right)$.

A natural question is whether DSF admits an $O\left(n^{1-\varepsilon}\right)$ approximation ratio. In particular, is there an $O(\sqrt{n})$-approximation algorithm? Our first result makes progress toward answering this question, by giving the first sublinear, in terms of $n$, approximation algorithm for the problem. The same algorithm, with minor modifications, also provides an approximation guarantee in terms of $m$, which for sparse graphs improves upon its guarantee in terms of $n$.
Theorem 1.1 DSF admits an $O\left(n^{\varepsilon} \cdot \min \left\{n^{4 / 5}, m^{2 / 3}\right\}\right)$-approximation scheme.
The algorithm of [3] for DSF does not extend to $k$-DSF; see the reasons for that in Section 1.3.1. Thus another natural question is: What is the best ratio possible for $k$-DSF in terms of $k$ ? We prove:
Theorem $1.2 k$-DSF admits an $O\left(k^{1 / 2+\varepsilon}\right)$-approximation scheme.
This improves the $\tilde{O}\left(k^{2 / 3}\right)$ ratio of [2], and almost matches the best approximation $O(\sqrt{k})$ known (in terms of $k$ ) for undirected graphs [14]. A striking feature of the state of the art of the $k$-Steiner Forest problem is that the ratios known for the directed and undirected cases are not that different in terms of $k$ : $O(\sqrt{k})$ for undirected graphs [14] versus $O\left(k^{1 / 2+\varepsilon}\right)$ in our paper. However, in terms of $n$, the difference $O(\sqrt{n})$ versus $O\left(n^{4 / 5+\varepsilon}\right)$ is still quite large.

A setpair is a pair $(S, T)$ of disjoint nonempty subsets of $V$. Chekuri et al. [3] gave an $O\left(\log ^{2} n \log ^{2}|\mathcal{D}|\right)$ approximation algorithm for the following generalization of the Group Steiner Tree problem:

## Group Steiner Forest (GSF)

Instance: An (undirected) graph $G=(V, E)$, edge costs $\{c(e): e \in E\}$, and a set $\mathcal{D}$ of setpairs in $V$.
Objective: Find a min-cost subgraph $H$ of $G$ such that for every setpair $(S, T) \in \mathcal{D}, H$ contains an $s t$-path for some $s \in S, t \in T$.
In the more general $k$-Group Steiner Forest ( $k$-GSF) problem, we are also given an integer $k \leq|\mathcal{D}|$, and it is only required that for (at least) $k$ setpairs $(S, T) \in \mathcal{D}, H$ contains an st-path for some $s \in S, t \in T$. Note that $k$-GSF also generalizes the (undirected) $k$-Steiner Forest problem, which is the particular case when every setpair in $\mathcal{D}$ is just a pair of nodes. The polylogarithmic approximation of [3] does not extend to $k$-GSF. Furthermore, $k$-GSF is unlikely to admit a polylogarithmic approximation ratio, otherwise, we would obtain a polylogarithmic approximation for (undirected) $k$-Steiner Forest. Recall that the best known ratio for the latter is $O(\min \{\sqrt{n}, \sqrt{k}\})$, and that a polylogarithmic ratio for it implies a polylogarithmic ratio for the Densest $k$-Subgraph problem [14]. $k$-GSF admits an easy (up to constants) approximation ratio preserving reduction to $k$-DSF. Thus by Theorem 1.2 we obtain the following extension of the $O(\sqrt{k})$-approximation for the (undirected) $k$-Steiner Forest problem:
Corollary 1.3 k-GSF admits an $O\left(k^{1 / 2+\varepsilon}\right)$-approximation scheme.
In fact, our results can be used to show that if the $k$-Group Steiner Tree problem admits an $\alpha$-approximation algorithm, then $k$-GSF admits an $O(\alpha \sqrt{k})$-approximation algorithm, implying an $\tilde{O}(\sqrt{k})$-approximation. [34].

The running time of our algorithm for $k$-DSF: We will show that if $k$-DST admits an $\alpha$ approximation in $T(n, k)$ time, then $k$-DSF admits an $O(\alpha \sqrt{k})$-approximation in $O\left(n k^{2} T(2 n+k, k)\right)$ time (assuming $T(n, k)$ is increasing in $k$ ). In particular, $k$-DSF admits an $O\left(k^{1 / 2+\varepsilon} / \varepsilon^{3}\right)$-approximation algorithm which runs in $O\left(n k^{2+4 / \varepsilon}(2 n+k)^{2 / \varepsilon}\right)$ time for any fixed $\varepsilon>0$. Using the specific properties of the $k$-DST algorithm of [2], the time complexity can be reduced to $O\left(n k^{1+4 / \varepsilon}(2 n+k)^{2 / \varepsilon}\right)$.
Comparing our DSF algorithm and the one of [3]: In addition to the above improvements, our $O\left(k^{1 / 2+\varepsilon}\right)$-approximation algorithm for $k$-DSF, when restricted to the special case of DSF, achieves the same ratio as [3] but is much simpler and much faster. The algorithm of [3] repeatedly solves linear programs while our algorithm can be seen as a reduction to $k$-DST and is purely combinatorial; this is the reason our running time is much lower. We achieve this by introducing a new notion of junction star-trees that simplifies matters.

### 1.3 Main new techniques

### 1.3.1 Junction star-trees and their advantages

The algorithm of [2] for $k$-DST accumulates low density directed trees until enough terminals are connected to the root. The density of a tree is its cost over the number of new terminals it connects. The idea of low-density junction trees was first invented for approximating Buy-at-Bulk problems [5], where it was applied to undirected graphs.

For the sake of Buy-at-Bulk, it was enough to define a junction tree as a collection of paths, all going via the same node, and sending a (possibly fractional) unit of $s_{i} t_{i}$-flow for "many" $s_{i}, t_{i}$ pairs at a "low" cost. The reason this definition suffices is that there are known methods to round such fractional solutions into trees of low cost with only polylogarithmic loss compared to the fractional value (see $[28,6]$ ).

For problems on directed graphs, it does not seem that we can easily use fractional flow methods to achieve a low ratio approximation algorithm. Even for DST, it is not clear if it is possible to round a fractional flow solution into a low cost out-branching. The only tool we have for tasks of finding low cost out- and in-branchings is the recursive greedy algorithm of [2]. Hence, in the directed setting a more careful definition of junction tree is used [3]:

Definition 1.1 An edge set $J$ in a directed graph is called junction tree if it is the union of an ingoing tree and an outgoing tree (not necessarily edge disjoint), both rooted at the same node $r$. The density of a junction tree w.r.t. a set $\mathcal{D}$ of ordered node pairs is its cost over the number of pairs from $\mathcal{D}$ it connects.

We present a few details of the algorithm of [3]. A simple averaging argument shows that in the optimal solution there is a node $r$ so that at least $\sqrt{k} s_{i} t_{i}$-paths go via it (otherwise, there is a path which forms a low density junction tree by itself [3]) giving an existence of a low density junction tree. ${ }^{1}$ The question is how to find such a low density junction tree. The non-trivial challenge is to "match" each "source" $s_{i}$ with the proper terminal $t_{i}$. A "naive" approach is guessing the root $r$ and

[^1]the number $k^{\prime}$ of sources in the junction-tree (which equals the number of terminals in it), and finding an in-branching with $k^{\prime}$ sources and an out-branching with $k^{\prime}$ terminals using [2]. This method fails because the sources in the in-branching and the terminals in the out-branching found may not match. In [3], this difficulty was overcomed using a "density type" linear program that "forces" the sources to match the terminals. See a simpler application of a density type LP in [5] for undirected graphs.

We overcome the above difficulty of matching $s_{i}$ and $t_{i}$ using "junction star-trees". A junction star-tree is an in-star with leaves $s_{i}$ entering a root $r$ joined to an out-branching covering the respective $t_{i}$. We force the $s_{i}, t_{i}$ to match by "attaching" each $s_{i}$ as a child of $t_{i}$ with a directed edge $t_{i} s_{i}$ of cost $c\left(s_{i} r\right)$. Thus, the $s_{i}$ becomes the terminal, and $s_{i}$ belongs to the solution if and only if $t_{i}$ does (see a more formal proof of this in Section 4). We show that the metric completion of the input graph $G$ always contains a junction star-tree of good density. Hence the problem is reduced to $k^{\prime}$-DST problem; we still need to guess the root $r$ and the number $k^{\prime}$ of pairs in the junction star-tree, but we do not need to use LP methods. Obviously, a drawback is that it is harder to prove the existence of a low density junction star-tree, see Section 4, than just the existence of a low density junction tree.

Another disadvantage of the LP method used by [3] is that it is unable to deal with the $k$-DSF problem. The LP may connect an arbitrary number of pairs, possibly many more than $k$. The use of junction star-trees allows us to use the algorithm of [2] for $k$-DST (by solving the $k^{\prime}$-DST problem, for all $k^{\prime} \leq k$ ) instead of the LP method, which in turn allows us to control the number of pairs connected.

### 1.3.2 A novel LP in the algorithm for DSF

Intuitively, a pair st $\in D$ is "good" if there are "many" nodes $r$ so that a "cheap" st-path via $r$ exists; otherwise, the pair is "bad". There are three main procedures in our sublinear algorithm for DSF:

1. The first procedure uses randomization to find a relatively small "junction subset" $R \subset V$ through which all good pairs can be connected. As $R$ is small, and the paths are cheap, we can show that the cost incurred in connecting all good pairs via $R$ is $\tilde{O}\left(n^{4 / 5}\right)$. opt. After all good pairs are connected, they are excluded from $\mathcal{D}$, and we remain with bad pairs only.
2. If in some optimal solution at least half of bad pairs are connected by "costly path" then we prove, by standard averaging, the existence of a low density junction-tree (as defined in [3]). A sub-graph with density close to the density of such a tree is found using the procedure of [3].
3. The difficult case is when the optimal solution connects most of the bad pairs by "cheap" paths. To handle this case, we formulate a novel LP-relaxation which asks to connect pairs by cheap paths only. This LP assigns capacity $x_{e}$ to every edge $e$ so that it will be possible to send a unit of $s_{i} t_{i}$-flow (separately for every $i$ ) along cheap paths, and so that $\sum_{e \in E} c(e) x_{e}$ is minimized. We show how to find approximate solutions for this LP in polynomial time, and that rounding up entries $x_{e}$ of large enough value gives a low density sub-graph.

Similarly, we can also think of a "good pair" as a pair of nodes such that many edges are involved in "cheap" paths connecting them. This idea give raise to an approximation guarantee in terms of $m$.

## 2 Preliminaries

### 2.1 The Greedy Algorithm

We use a known result about the performance of a Greedy Algorithm for the following type of problems:

## Covering Problem

Instance: A groundset $E$ and non-negative functions $\nu, c$ on $2^{E}$, given by an evaluation oracle.
Objective: Find an $F \subseteq E$ with $\nu(F)=0$ and $c(F)$ minimized.
We call $\nu$ the deficiency function (it measures how far is $F$ from being a feasible solution) and $c$ the cost function.

Definition 2.1 Let $F \subseteq E$ be a partial solution (partial cover) for an instance of Covering ProbLEM and let $J \subseteq E$. Let $\rho(x)$ be a positive function, and let opt be the optimal solution value for Covering Problem. We say that $J \subseteq E$ obeys the $\rho(x)$-Density Condition if:

$$
\begin{equation*}
\sigma_{F}(J)=\frac{c(J)}{\nu(F)-\nu(F \cup J)} \leq \mathrm{opt} \cdot \frac{\rho(\nu(F))}{\nu(F)} \tag{1}
\end{equation*}
$$

The quantity $\sigma_{F}(J)$ in (1) is the density of $J$ (w.r.t. F). The Greedy Algorithm starts with $F=\emptyset$ and iteratively adds to $F$ a subset $J \subseteq E$ obeying (1). A set-function $f$ on $2^{E}$ is decreasing if $f\left(F_{2}\right) \leq f\left(F_{1}\right)$ for any $F_{1} \subseteq F_{2} \subseteq E$, and subadditive if $f\left(F_{1} \cup F_{2}\right) \leq f\left(F_{1}\right)+f\left(F_{2}\right)$ for any $F_{1}, F_{2} \subseteq E$. The following statement is well known (e.g., see a slightly weaker version in [2]).

Theorem 2.1 If $\nu$ is decreasing, $c$ is subadditive, and $\rho(x) / x$ is a decreasing function, then the Greedy Algorithm computes a solution $F$ with:

$$
\begin{equation*}
c(F) \leq \mathrm{opt} \cdot \int_{0}^{\nu(\emptyset)} \frac{\rho(x)}{x} d x . \tag{2}
\end{equation*}
$$

In our setting, the groundset is the set $E$ of edges of the graph. For every partial solution $F \subseteq E$, the deficiency $\nu(F)$ of $F$ is the number of ordered pairs not connected by $F$. Formally, $\nu(F)=$ $\max \{k-|\mathcal{D}(F)|, 0\}$, where $\mathcal{D}(F)$ denotes the set of pairs from $\mathcal{D}$ connected by $F$. Clearly, $\nu$ is decreasing, and $c$ is subadditive.

### 2.2 Some simple reductions

We briefly describe some well known reductions to be used later that we can apply with negligible loss (in time complexity or approximation ratio) on a given $k$-DSF instance.

Reduction 1 We may assume that we know $\tau$ such that opt $\leq \tau \leq 2 \cdot$ opt.
This can be done by exhaustively checking all values $\tau \in\left\{1,2,4, \ldots, 2^{\left\lceil\log _{2} c(E)\right\rceil}\right\}$; we omit the (well known) details, and for simplicity of exposition assume that $\tau=\mathrm{opt}$.

Reduction 2 Let $S, T$ be the sets of first and second nodes in pairs of $\mathcal{D}$, respectively. We may assume that $S \cap T=\emptyset$ and that no edge enters $S$ or leaves $T$.

This can be achieved by adding for every node $v$ two new nodes $s_{v}, t_{v}$ with edges $s_{v} v, v t_{v}$ of cost 0 each, and replacing every ordered pair $(u, v) \in \mathcal{D}$ by the pair $\left(s_{u}, t_{v}\right)$.

Reduction 3 We may assume that $G$ is transitively closed and that the costs are metric.
This is achieved by applying metric completion.

## 3 A sublinear algorithm for DSF (Proof of Theorem 1.1)

In this section we describe an $O\left(n^{4 / 5+\varepsilon}\right)$-approximation scheme for DSF. The $O\left(m^{2 / 3+\varepsilon}\right)$-approximation scheme uses a similar method, and is shortly described in Section 3.4.

Given an instance of DSF assume that Reductions 1 and 2 from Section 2.2 are implemented. Recall that in DSF $k=|D|$. In what follows, let $p, \alpha, \ell$ be parameters eventually set to:

$$
p=2 \ln k / n^{2 / 5}, \quad \alpha=n^{2 / 5}, \quad \ell=\tau / \alpha^{2}
$$

Definition 3.1 For a graph $H$, let $\operatorname{dist}_{H}(u, v)$ denote the minimum cost of a uv-path in $H$. A path $P$ is short if $c(P) \leq \ell$, and long otherwise. For $(s, t) \in D$, let $U(s, t)=\left\{u \in V: \operatorname{dist}_{G}(s, u)\right.$, $\left.\operatorname{dist}_{G}(u, t) \leq \ell\right\}$. A pair $(s, t) \in D$ is good if $|U(s, t)| \geq \alpha$, and is bad otherwise.

### 3.1 Connecting the good pairs

Lemma 3.1 There exists a polynomial time algorithm that given an instance of DSF finds an edge set $F$ of cost $c(F) \leq 4 p n^{2} \ell=\tilde{O}\left(n^{4 / 5}\right) \cdot \tau$ that connects all good pairs.

Proof: Form a set $R \subseteq V$ by picking every node $v \in V$ into $R$ with probability $p$. For a given good pair $(s, t)$ we have:

$$
\operatorname{Pr}[R \cap U(s, t)=\emptyset] \leq(1-p)^{\alpha} \leq \frac{1}{k^{2}}
$$

By the union bound, the probability that $R \cap U(s, t) \neq \emptyset$ for every good pair $(s, t)$ is at least $1-1 / k$. Notice that $|R|$ is a random variable with binomial distribution $B(n, p)$, thus $E(|R|)=p n$. Using the Chernoff Bound we get:

$$
\operatorname{Pr}[|R| \leq 2 p n]=\operatorname{Pr}[|R| \leq 2 \cdot E(|R|)]>1-e^{-p n / 4}
$$

For $p n / 4 \geq \ln k$ we get that with high probability both $|R| \leq 2 p n$ and $R \cap U(s, t) \neq \emptyset$ for every good pair $(s, t)$ (this procedure can be derandomized using the method of conditional probabilities). We connect by a short path every node $s \in S$ to every node $v \in R$, if such path exists. Similarly, we connect by a short path every node $v \in R$ to every node $t \in T$, if such path exists. Let $H$ be the sub-graph constructed by the above procedure. Clearly, $H$ connects all good pairs. As $|S|+|T| \leq 2 n$, we get that $c(H) \leq|R| \cdot 2 n \cdot \ell \leq 2 p n \cdot 2 n \cdot \ell=4 p n^{2} \tau / \alpha^{2}=\tau \cdot \tilde{O}\left(n^{4 / 5}\right)$.

### 3.2 Connecting the bad pairs

After all good pairs are connected using the algorithm of Lemma 3.1, they are excluded from $\mathcal{D}$, and we remain with bad pairs only.

Lemma 3.2 There exists an algorithm that given a DSF instance without good pairs and a constant $\varepsilon>0$, computes in polynomial time an edge set $J \subseteq E$ of density $O\left(n^{4 / 5+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$.

In the rest of this subsection we prove Lemma 3.2. We compute two edge sets using two different algorithms, and choose among them the one with lower density. For analysis purpose, let $H$ be some fixed optimal solution, so $c(H)=\mathrm{opt}=\tau$. Let $L=\left\{(s, t) \in D: \operatorname{dist}_{H}(s, t) \geq \ell\right\}$. We will consider two cases: $|L| \geq|\mathcal{D}| / 2$ and $|\mathcal{D}-L|>|\mathcal{D}| / 2$. Proposition 3.4 handles the first case.

Lemma 3.3 ([3]) The problem of finding a minimum density junction tree admits an $O\left(k^{\varepsilon}\right)$-approximation scheme.

Proposition 3.4 $H$ contains a junction tree $J$ of density

$$
\sigma(J) \leq \frac{\tau}{\ell} \cdot \frac{\tau}{|L|}=n^{4 / 5} \cdot \frac{\tau}{|L|}
$$

Hence if $|L| \geq|\mathcal{D}| / 2$, the algorithm of [3] finds a junction tree $J$ of density $O\left(n^{4 / 5+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$.
Proof: Let $\Pi(L)$ be a set of paths in $H$ corresponding to the pairs in $L$. The sum of the costs of the paths in $\Pi(L)$ is at least $|L| \cdot \ell$. Since the paths of $\Pi(L)$ are in $H$, there must be an edge of $H$ belonging to at least $|L| \cdot \ell / \tau$ paths. This implies that there is a junction-tree in $H$ connecting at least $|L| \cdot \ell / \tau$ pairs from $\Pi(L)$. The density of this junction-tree is at-most $c(H) /(|L| \cdot(\ell / \tau)) \leq(\tau /|L|) \cdot(\tau / \ell)$, as claimed.

Now suppose that $|L|<|\mathcal{D}| / 2$, so $|\mathcal{D}-L|>|\mathcal{D}| / 2$. Consider the following LP-relaxation (LP1) for the problem of connecting at least $k^{\prime} \leq|\mathcal{D}-L|$ pairs from $\mathcal{D}=\left\{\left(s_{1}, t_{1}\right), \ldots,\left(s_{k}, t_{k}\right)\right\}$. Intuitively, (LP1) decides on a capacity $x_{e}$ for every $e \in E$ and an amount $y_{i}$ of $s_{i} t_{i}$-flow. The sum of the $y_{i}$ 's is at least $k^{\prime}$. The main restriction is that the flow has to be delivered on (simple) paths of cost $\leq \ell$. This is done as follows. Let $\Pi(i)$ be the set of (simple) $s_{i} t_{i}$-paths in $G$ of cost $\leq \ell$, and let $\Pi=\bigcup_{i} \Pi(i)$. For every $i$, decompose the final $s_{i} t_{i}$-flow in the graph into flow paths. For every $P \in \Pi(i)$, the variable $f_{P}$ is the amount of $s_{i} t_{i}$-flow through $P$. The total $s_{i} t_{i}$-flow equals the sum of the flows on the paths in $\Pi(i)$, namely, $y_{i}=\sum_{P \in \Pi(i)} f_{P}$. For every $i$ and $e \in E$, the capacity constraint is $\sum_{\Pi(i) \ni P \ni e} f_{P} \leq x_{e} ;$ namely, the total $s_{i} t_{i}$-flow through $e$ is at most $x_{e}$. Note that it holds for every pair separately, namely, it may not be possible to deliver simultaneously flows $y_{i}$ and $y_{i^{\prime}}$ (for some $i \neq i^{\prime}$ ).

$$
\begin{array}{rlrl}
\text { (LP1) } \min & \sum_{e \in E} c(e) x_{e} & & \\
\text { s.t. } & \sum_{i} y_{i} & \geq k^{\prime} & \\
& \sum_{\Pi(i) \ni P \ni e} f_{P} & \leq x_{e} & \forall i, e \in E \\
\sum_{P \in \Pi(i)} f_{P} & =y_{i} & \forall i \\
y_{i}, x_{e} & \leq 1 & \forall i, e \in E \\
y_{i}, f_{P}, x_{e} & \geq 0 & \forall i, P \in \Pi, e \in E
\end{array}
$$

The corresponding dual LP is:
(LP2) $\max \sum_{e \in E} x_{e}+\sum_{i} y_{i}-W \cdot k^{\prime}$
s.t. $\quad \sum_{i} z_{i, e}+c(e) \leq x_{e} \quad \forall e \in E$
$y_{i}+w_{i} \geq W \quad \forall i$
$w_{i} \leq \sum_{e \in P} z_{i, e} \quad \forall i, P \in \Pi(i)$
$W, x_{e}, y_{i}, z_{i, e} \geq 0 \quad \forall i, e \in E$

Lemma 3.5 For any $k^{\prime} \leq|D-L|$ the optimal value of (LP1) is at most opt. Furthermore, a solution for (LP1) of value $\leq(1+\varepsilon) \cdot$ opt can be found in polynomial time.

Proof: The first statement is obvious, as (LP1) is a relaxation for the problem. We will show how to find an approximate solution in polynomial time. Although the number of variables in (LP1) might be exponential, any basic feasible solution to it has $O(|\mathcal{D}| \cdot m)$ non-zero variables. Now, if we had a polynomial time separation oracle for (LP2), we could compute an optimal solution to (LP1) (the non-zero entries) in polynomial time. The number of non-zero entries in such a computed solution is polynomial in $O(|\mathcal{D}| \cdot m)$. There is a polynomial number of dual constraints of all types, except for the constraints of the form $w_{i} \leq \sum_{e \in P} z_{i, e}$. Unfortunately, for these constraints, a polynomial time separation oracle may not exist, since the separation problem defined by a specific pair $\left(s_{i}, t_{i}\right)$ is equivalent to the following problem, which is NP-hard, see [27]:

## Restricted Shortest Path (RSP)

Instance: A directed graph $G=(V, E)$, transition times $\{z(e): e \in E\}$, lengths $\{\ell(e): e \in E\}$, a pair $(s, t)$, and an integer $Z$.
Objective: Find a minimum length st-path $P$ such that $\sum_{e \in P} z(e) \leq Z$.
RSP admits an FPTAS (see [17] and an improved result in [27]), therefore we can compute an approximate separation oracle, which for any $\varepsilon>0$ checks whether there exists a path $P \in \Pi(i)$ so that $w_{i} \leq \sum_{e \in P} z_{i, e} /(1+\varepsilon)$. This implies that we can solve the following linear program in time polynomial in $1 / \varepsilon$ and the size of the original DSF problem:

$$
\begin{aligned}
\text { (LP3) } \max \sum_{e \in E} x_{e}+\sum_{i} y_{i}-W & \cdot k^{\prime} & & \\
\text { s.t. } \sum_{i} z_{i, e}+c(e) & \leq x_{e} & & \forall e \in E \\
y_{i}+w_{i} & \geq W & & \forall i \\
w_{i} & \leq \sum_{e \in P} z_{i, e} /(1+\varepsilon) & & \forall i, P \in \Pi(i) \\
W, x_{e}, y_{i}, z_{i, e} & \geq 0 & & \forall i, e \in E
\end{aligned}
$$

Thus we can also solve the dual of (LP3), which is:

$$
\begin{array}{rlrl}
\text { (LP4) } \min & \sum_{e \in E} c(e) x_{e} & & \\
\text { s.t. } & \sum_{i} y_{i} & \geq k^{\prime} & \\
& \sum_{\Pi(i) \ni P \ni e} f_{P} & \leq x_{e} \cdot(1+\varepsilon) & \forall i, e \in E \\
\sum_{P \in \Pi(i)} f_{P} & =y_{i} & \forall i \\
& y_{i}, x_{e} & \leq 1 & \forall i, e \in E \\
y_{i}, f_{P}, x_{e} & \geq 0 & \forall i, P \in \Pi, e \in E
\end{array}
$$

Let opt $(\varepsilon)$ denote the optimal value of $(\operatorname{LP} 4)$. Clearly, opt $(\varepsilon) \leq$ opt. Note that if $x(\varepsilon)$ is a feasible solution to (LP4), then by replacing the value of every variable $x_{e}$ in $x(\varepsilon)$ by $\min \left\{1, x_{e} \cdot(1+\varepsilon)\right\}$ we get a new solution $x$ which is a feasible solution to (LP1). The value of such $x$ is at most $(1+\varepsilon) \cdot \mathbf{o p t}(\varepsilon) \leq(1+\varepsilon) \cdot$ opt.
Lemma 3.6 Let $x, y$ be a feasible solution to (LP1) and let $\beta$ be any number obeying $0 \leq \beta<k^{\prime} /|\mathcal{D}|$. Then at most $\left(|\mathcal{D}|-k^{\prime}\right) /(1-\beta)$ pairs in $\mathcal{D}$ have flow $y_{i}<\beta$. Thus, the number of pairs in $\mathcal{D}$ that
have flow $y_{i} \geq \beta$ is at least:

$$
\left|\left\{i: y_{i} \geq \beta\right\}\right| \geq|\mathcal{D}|-\frac{|\mathcal{D}|-k^{\prime}}{1-\beta}=\frac{k^{\prime}-\beta|\mathcal{D}|}{1-\beta}
$$

Proof: If more than $\left(|\mathcal{D}|-k^{\prime}\right) /(1-\beta)$ pairs in $\mathcal{D}$ have flow strictly less than $\beta$, then the sum of the flows between all pairs must be strictly less than:

$$
\frac{|\mathcal{D}|-k^{\prime}}{1-\beta} \cdot \beta+\left(|\mathcal{D}|-\frac{|\mathcal{D}|-k^{\prime}}{1-\beta}\right) \cdot 1=|\mathcal{D}|+(\beta-1) \cdot \frac{|\mathcal{D}|-k^{\prime}}{1-\beta}=k^{\prime}
$$

This is a contradiction, since in any feasible solution of (LP1), the sum of the flows between all pairs must be at least $k^{\prime}$.

Lemma 3.7 Let ( $x, y$ ) be any feasible solution to (LP1) and let $\beta$ be any number obeying $0 \leq \beta<1$. If $y_{i} \geq \beta$ for some $i$ then $J=\left\{e \in E: x_{e} \geq 4 \beta / \alpha^{2}\right\}$ contains an $s_{i} t_{i}$-path.
Proof: We claim that $C \cap J \neq \emptyset$ for every $s_{i} t_{i}$-cut $C$. Suppose to the contrary that $C \cap J=\emptyset$ for some $s_{i} t_{i}$-cut $C$, namely, $x_{e}<4 \beta / \alpha^{2}$ for every $e \in C$. Thus $|C| \geq \alpha^{2} / 4$, since $\sum_{e \in C} x_{e} \geq y_{i} \geq \beta$. Every edge $e=u v \in C$ that carries a positive amount of $s_{i} t_{i}$-flow belongs to some short $s_{i} t_{i}$-path, thus $u, v \in U\left(s_{i}, t_{i}\right)$. Consequently, $U\left(s_{i}, t_{i}\right)$ contains end nodes of at least $\alpha^{2} / 4$ edges of the cut $C$, implying that $U\left(s_{i}, t_{i}\right)$ contains at least $2 \sqrt{\alpha^{2} / 4}=\alpha$ nodes. Thus $\left(s_{i}, t_{i}\right)$ is a good pair, contradicting our assumption that all the pairs are bad.
Corollary 3.8 Assuming $k^{\prime} \leq|\mathcal{D}-L|$, let $(x, y)$ be any feasible solution to (LP1) found using Lemma 3.5. Then for any $0 \leq \beta<k^{\prime} /|\mathcal{D}|$, the edge set $J=\left\{e \in E: x_{e} \geq 4 \beta / \alpha^{2}\right\}$ has density at most:

$$
\frac{\alpha^{2} \mathrm{opt} \cdot(1+\varepsilon)}{4 \beta} \cdot \frac{(1-\beta)}{k^{\prime}-\beta|\mathcal{D}|}
$$

In particular, for $k^{\prime}=|\mathcal{D}| / 2 \leq|\mathcal{D}-L|$ and $\beta=1 / 4$, the density of $J$ is at most $3 \alpha^{2} \cdot \mathrm{opt} \cdot(1+\varepsilon) / \mathcal{D}=$ $O\left(n^{4 / 5}\right) \cdot \mathrm{opt} /|\mathcal{D}|$.
Proof: Since $k^{\prime} \leq|D-L|$, the value of (LP1) is at most opt • $(1+\varepsilon)$, by Lemma 3.5. Thus $c(J) \leq$ opt $\cdot(1+\varepsilon) /\left(4 \beta / \alpha^{2}\right)=$ opt $\cdot(1+\varepsilon) \alpha^{2} /(4 \beta)$. By Lemmas 3.6 and $3.7,|\mathcal{D}(J)| \geq\left(k^{\prime}-\beta|\mathcal{D}|\right) /(1-\beta)$. Thus:

$$
\sigma(J)=\frac{c(J)}{|\mathcal{D}(J)|} \leq \frac{\mathrm{opt} \cdot(1+\varepsilon) \alpha^{2} /(4 \beta)}{\left(k^{\prime}-\beta|\mathcal{D}|\right) /(1-\beta)}=\frac{\alpha^{2} \mathrm{opt} \cdot(1+\varepsilon)}{4 \beta} \cdot \frac{(1-\beta)}{k^{\prime}-\beta|\mathcal{D}|}
$$

Proof of Lemma 3.2: We execute two algorithms to compute edge sets $J^{\prime}, J^{\prime \prime}$ and choose among them the one with the better density. The set $J^{\prime}$ is computed using the algorithm of Lemma 3.3. The set $J^{\prime \prime}$ is computed using the algorithm of Corollary 3.8 with parameters $k^{\prime}=|\mathcal{D}| / 2$ and $\beta=1 / 4$. If $|L| \geq|\mathcal{D}| / 2$ then the density of $J^{\prime}$ is $O\left(n^{4 / 5+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$. Otherwise, since $|\mathcal{D}-L| \geq|\mathcal{D}| / 2$, the density of $J^{\prime \prime}$ is $O\left(n^{4 / 5}\right) \cdot \tau /|\mathcal{D}|$. In both cases, one of $J^{\prime}, J^{\prime \prime}$ has density $O\left(n^{4 / 5+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$.

### 3.3 Putting everything together

Implement Reductions 1 (so we know opt $\leq \tau \leq 2 \mathrm{opt}$ ) and 2 . Then the entire algorithm is as follows:

1. Find an edge set $F$ as in Lemma 3.1, and exclude all good pairs from $\mathcal{D}$.
2. While $F$ is not a feasible solution do:

- Find an edge set $J$ as in Lemma 3.2;
$-F \leftarrow F+J ;$
- $\mathcal{D} \leftarrow \mathcal{D}-\mathcal{D}(J)$.

EndWhile
3. Return F.

The reductions incur only a constant loss in the approximation ratio. The total cost of the edges added at Step 1 is $\tilde{O}\left(n^{4 / 5}\right) \cdot \tau$, by Lemma 3.1. Step 2 is essentially the Greedy Algorithm with $\rho=O\left(n^{4 / 5+\varepsilon}\right)$, by Lemma 3.2. Thus by Theorem 2.1, the total cost of the edges added at Step 2 is $O\left(n^{4 / 5+\varepsilon}\right) \cdot \tau=O\left(n^{4 / 5+\varepsilon}\right) \cdot$ opt.

### 3.4 An $O\left(m^{2 / 3+\varepsilon}\right)$-approximation scheme for DSF

In this subsection we show how to modify the above algorithm, to achieve an approximation ratio of $O\left(m^{2 / 3+\varepsilon}\right)$. We assume that the input graph is connected, and therefore $n=O(m)$, otherwise we can process each connected component separately. Let us update the values of the parameters of the algorithm, as follows:

$$
p=2 \ln k / m^{2 / 3}, \quad \alpha=m^{2 / 3}, \quad \ell=\tau / \alpha .
$$

In order to reflect the fact that we are now interested in edges, rather than in nodes, we change the definition of $U(s, t)$ to:
Definition 3.2 For each pair $s, t$ of nodes, let $U(s, t)$ be the set of edges involved in any short path from s to $t$.
Notice that we keep the definition of good and bad pairs, a pair $(s, t)$ is a good pair if and only if $|U(s, t)| \geq \alpha$. The following Lemma is the equivalent of Lemma 3.1:

Lemma 3.9 There exists a polynomial time algorithm that given an instance of DSF finds an edge set $F$ of cost $c(F) \leq 6 p n m \ell=\tilde{O}\left(n / m^{1 / 3}\right) \cdot \tau=\tilde{O}\left(m^{2 / 3}\right) \cdot \tau$ that connects all good pairs.
Proof: Form a set $R \subseteq E$ by picking every edge $e$ such that $c(e) \leq \ell$ into $R$ with probability $p$. Then, connect by a short path every source $s \in S$ to the beginning of every edge $e \in R$, if such path exists. Similarly, connect by a short path the end of every edge $e \in R$ to every terminal $t \in T$, if such path exists. Let $H$ be the sub-graph constructed by the above procedure. The same arguments used in the proof of Lemma 3.1 show that with high probability $H$ connects all the good pairs and $|R| \leq 2 p m$. Notice that an edge $e$ with $c(e)>\ell$ cannot be in $U(s, t)$ for any pair $s, t)$, therefore, the total cost of the edges in $R$ is at most $|R| \cdot \ell \leq 2 p m \ell$. As $|S|+|T| \leq 2 n$, the cost of the paths we add to $H$ after $R$ is determined is no more than $|R| \cdot 2 n \cdot \ell \leq 4 p n m \ell$.

To complete the algorithm we need the following Lemma, which is equivalent to Lemma 3.2:
Lemma 3.10 There exists an algorithm that given a DSF instance without good pairs and a constant $\varepsilon>0$, computes in polynomial time an edge set $J \subseteq E$ of density $\tilde{O}\left(m^{2 / 3+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$.

Again, we make a distinction between the two cases: $|L| \geq|\mathcal{D}| / 2$ and $|\mathcal{D}-L| \geq|\mathcal{D}| / 2$, where $L$ is defined as before. The next statement tells us that in the first case we can find a junction tree with the required density; the proof is exactly the same as the proof of Proposition 3.4, up to the changes we made to the parameters, and it is, therefore, omitted.

Proposition 3.11 $H$ contains a junction tree $J$ of density at most

$$
\sigma(J) \leq \frac{\tau}{\ell} \cdot \frac{\tau}{|L|}=m^{2 / 3} \cdot \frac{\tau}{|L|}
$$

Hence if $|L| \geq|\mathcal{D}| / 2$, the algorithm of [3] finds a junction tree $J$ of density $O\left(m^{2 / 3+\varepsilon}\right) \cdot \tau /|\mathcal{D}|$.
Now consider the case $|\mathcal{D}-L| \geq|\mathcal{D}| / 2$. Looking back at (LP1), after the changes implied by the new set of short paths, we notice that Lemmas 3.5 and 3.6 still hold.

Lemma 3.12 (Equivalent of Lemma 3.7) Let ( $x, y$ ) be any feasible solution to (LP1) and let $0<$ $\beta \leq 1$. If $y_{i} \geq \beta$ for some $i$ then $J=\left\{e \in E: x_{e} \geq \beta / \alpha\right\}$ contains an $s_{i} t_{i}$-path.

Proof: We claim that $C \cap J \neq \emptyset$ for every $s_{i} t_{i}$-cut $C$. Suppose to the contrary that $C \cap J=\emptyset$ for some $s_{i} t_{i}$-cut $C$, namely, $x_{e}<\beta / \alpha$ for every $e \in C$. Thus $|C|$ contains at least $\alpha$ edges of positive $s_{i} t_{i}$-flow, since $\sum_{e \in C} x_{e} \geq y_{i} \geq \beta$. Every edge $e$ carrying a positive amount of $s_{i} t_{i}$-flow belongs to some short $s_{i} t_{i}$-path, thus $e \in U\left(s_{i}, t_{i}\right)$. Consequently, $U\left(s_{i}, t_{i}\right)$ contains at least $\alpha$ edges. Thus ( $s_{i}, t_{i}$ ) is a good pair, contradicting our assumption that all pairs are bad.
Corollary 3.13 (Equivalent of Corollary 3.8) Assuming $k^{\prime} \leq|\mathcal{D}-L|$, let ( $x, y$ ) be any feasible solution to (LP1) found using Lemma 3.5. Then for any $0<\beta<k^{\prime} /|\mathcal{D}|$, the edge set $J=\{e \in E$ : $\left.x_{e} \geq \beta / \alpha\right\}$ has density at most:

$$
\frac{\alpha \mathrm{opt} \cdot(1+\varepsilon)}{\beta} \cdot \frac{(1-\beta)}{k^{\prime}-\beta|\mathcal{D}|}
$$

In particular, for $k^{\prime}=|\mathcal{D}| / 2 \leq|\mathcal{D}-L|$ and $\beta=1 / 4$, the density of $J$ is at most $3 \alpha \cdot \mathrm{opt} \cdot(1+\varepsilon) /(4 \mathcal{D})=$ $O\left(m^{2 / 3}\right) \cdot \mathrm{opt} /|\mathcal{D}|$.

Proof: Since $k^{\prime} \leq|\mathcal{D}-L|$, the value of (LP1) is at most opt • $(1+\varepsilon)$, by Lemma 3.5. Thus $c(J) \leq$ opt $\cdot(1+\varepsilon) /(\beta / \alpha)=$ opt $\cdot(1+\varepsilon) \alpha / \beta$. By Lemmas 3.6 and $3.12,|\mathcal{D}(J)| \geq\left(k^{\prime}-\beta|\mathcal{D}|\right) /(1-\beta)$. Thus:

$$
\sigma(J)=\frac{c(J)}{|\mathcal{D}(J)|} \leq \frac{\mathrm{opt} \cdot(1+\varepsilon) \alpha / \beta}{\left(k^{\prime}-\beta|\mathcal{D}|\right) /(1-\beta)}=\frac{\alpha \mathrm{opt} \cdot(1+\varepsilon)}{\beta} \cdot \frac{(1-\beta)}{k^{\prime}-\beta|\mathcal{D}|}
$$

Proof of Lemma 3.10: The proof is the same as that of Lemma 3.2, when Corollary 3.8 is replaced by Corollary 3.13, and Proposition 3.4 is replaced by Proposition 3.11.

In conclusion, the approximation scheme we get is the same as the one described in Section 3.3, with two differences:

- The good pairs are connected in step 1 as in Lemma 3.9.
- The edge set $J$ in step 2 is found as in Lemma 3.10.

Using a similar analysis to the one in Section 3.3, one can show that this scheme has an approximation ratio of $O\left(m^{2 / 3+\varepsilon}\right)$. This completes the proof of Theorem 1.1.

## 4 Algorithm for $k$-DSF (Proof of Theorem 1.2)

This section is organized as follows: Section 4.1 defines the notation of "junction star-trees" and proves the "The Junction Star-Tree Theorem" which ensures the existence of a good density junction star-tree in the metric completion of any graph. Section 4.2 describes our algorithm for $k$-DSF which based on this theorem.

### 4.1 Junction star-trees

Definition 4.1 Let $G$ be a directed graph with a set $\mathcal{D}=\left\{\left(s_{1}, t_{1}\right), \ldots,\left(s_{|\mathcal{D}|}, t_{|\mathcal{D}|}\right)\right\}$ of ordered pairs; $S=\left\{s_{1}, \ldots, s_{|\mathcal{D}|}\right\}$ are sources and $T=\left\{t_{1}, \ldots, t_{|\mathcal{D}|}\right\}$ are terminals. A subgraph $J$ of $G$ is a junction star-tree if it is the union of an out-branching $J_{T}$ rooted at $r$ in $(G-S) \cup\{r\}$ and a star $J_{S}$ ingoing to $r$ in $(G-T) \cup\{r\}$.

See Section 1.3.1 for intuition about junction star-trees. Our main interest will be in the case where the leaves of $J_{S}$ are the set of sources corresponding to the terminals of $J_{T}$. In the rest of this subsection we will prove the following statement, which is used in the algorithm presented in the next subsection, and which we believe is of independent interest.

Theorem 4.1 (The Junction Star-Tree Theorem) Let $H=(V, E)$ be a graph with edge costs $\{c(e): e \in E\}$ containing a set $\Pi$ of $k$ paths connecting a set $\mathcal{D} \subseteq S \times T$ of $k$ node pairs, so that $S \cap T=\emptyset$ and so that no edge enters $S$ or leaves $T$. If $c(P) \geq c(H) / g$ for every $P \in \Pi$ then the metric completion of $H$ contains a junction star-tree $J$ of density at most:

$$
\begin{equation*}
\frac{c(J)}{|\mathcal{D}(J)|} \leq c(H) \cdot\left(\frac{g}{k}+\frac{2}{g}\right) \tag{3}
\end{equation*}
$$

For every st-path $P \in \Pi$, the truncated path $\bar{P}$ of $P$ is the maximal $s v$-subpath of $P$ so that $c(\bar{P})<c(H) / g$. Let $e_{P}$ be the edge in $P-\bar{P}$ leaving the last node of $\bar{P}$. Since $c(P) \geq c(H) / g$, then by the definition of $\bar{P}: e_{P}$ always exists, and $c\left(\bar{P}+e_{P}\right) \geq c(H) / g$. Let $\bar{\Pi}=\{\bar{P}: P \in \Pi\}$.
Definition 4.2 We say that two (not necessarily different) truncated paths in $\bar{\Pi}$ collide if they have a node in common.
Lemma 4.2 There exists a partition $\overline{\mathcal{P}}_{1}, \ldots, \overline{\mathcal{P}}_{q}$ of $\bar{\Pi}$ into $q \leq g$ parts, and a set of pairwise noncolliding paths $\left\{\bar{P}_{i} \in \overline{\mathcal{P}}_{i}: i=1, \ldots, q\right\}$, such that $\bar{P}_{i}$ collides with every path in $\overline{\mathcal{P}}_{i}, i=1, \ldots, q$. Thus there is a path $\bar{P} \in \bar{\Pi}$ colliding with at least $\ell \geq k / g$ paths in $\bar{\Pi}$.

Proof: We will construct the partition iteratively. Assuming that at the end of iteration $i-1$ we constructed a subpartition $\left\{\overline{\mathcal{P}}_{1}, \ldots, \overline{\mathcal{P}}_{i-1}\right\}$ of $\bar{\Pi}$, which is not yet a partition of $\bar{\Pi}$, in iteration $i$ perform two steps:

1. Pick a path $\bar{P}_{i} \in \bar{\Pi}$ which does not belong to any part yet, and place it in a new part $\overline{\mathcal{P}}_{i}$.
2. Add to $\overline{\mathcal{P}}_{i}$ every path that collides with $\bar{P}_{i}$ and does not belong to any other part yet.

By the construction, it is clear that eventually we will get a partition of $\bar{\Pi}$, such that $\bar{P}_{i}$ collides with every path in $\overline{\mathcal{P}}_{i}$ for every $i$, and that $\left\{\bar{P}_{i}\right\}_{i=1}^{q}$ are pairwise non-colliding. Hence we only need to

Figure 1: (a) The trees $J_{1}, \ldots, J_{d}$ hanged on the path $\bar{P}$; the trees are edge disjoint, but might not be node disjoint; some of the trees might consist of the root only. (b) Illustration of property 3 in Lemma 4.3 and the "shortcut" in the proof of Corollary 4.4.
show that the number $q$ of parts is bounded by $g$. Let $e_{i}=e_{P_{i}}, i=1, \ldots, q$. Note that since $\bar{P}_{1}, \ldots, \bar{P}_{q}$ are pairwise node disjoint, the paths $\bar{P}_{1}+e_{1}, \ldots, \bar{P}_{q}+e_{q}$ are pairwise edge-disjoint. Thus their total cost is at most $c(H)$. Since $c\left(\bar{P}_{i}+e_{i}\right) \geq c(H) / g$ for every $i$, the statement follows.

Focus on a pair of a path $\bar{P} \in \bar{\Pi}$ and a set $\overline{\mathcal{P}}=\left\{\bar{P}_{1}, \ldots, \bar{P}_{\ell}\right\}$ of $\ell \geq k / g$ truncated paths colliding with $\bar{P}(\bar{P} \in \overline{\mathcal{P}})$, whose existence is guaranteed by Lemma 4.2. Let $\mathcal{P}=\left\{P_{1}, \ldots, P_{\ell}\right\} \subseteq \Pi$ be the set of corresponding non-truncated paths. Let $\bar{S}=\left\{s_{1}, \ldots, s_{\ell}\right\}$ and $\bar{T}=\left\{t_{1}, \ldots, t_{\ell}\right\}$ be the sets of sources and terminals of the paths in $\mathcal{P}$, respectively. Let $r_{1}, \ldots, r_{d}$ be the sequence of nodes of $\bar{P}$ arranged in reverse order; $r_{d}$ is the first node of $\bar{P}, r_{d-1}$ is the second, and so on; the last node of $\bar{P}$ is $r_{1}$ (see Fig. 1(a)).
Lemma 4.3 There exists in $H$ a family $J_{1}, \ldots, J_{d}$ of pairwise edge disjoint trees so that (see Fig. 1(b)):

1. Every $J_{i}$ is rooted at $r_{i}, i=1, \ldots, d$.
2. Every $t \in \bar{T}$ belongs exactly one tree $J_{i}, 1 \leq i \leq d$.
3. If $t \in \bar{T} \cap J_{i}$ and $(s, t) \in \mathcal{D}$, then there is $m \geq i$ so that $r_{m}$ belongs to a path in $\overline{\mathcal{P}}$ starting at $s$.

Proof: We construct the trees iteratively. $J_{1}$ is any inclusion minimal tree in $H$ rooted at $r_{1}$ that contains the set $T_{1}$ of all the terminals in $\bar{T}$ that are reachable in $H$ from $r_{1} . J_{2}$ is any inclusion minimal tree in $H$ rooted at $r_{2}$ that contains the set $T_{2}$ of all the terminals in $\bar{T}-T_{1}$ that are reachable in $H$ from $r_{2}$. And, in general, $J_{i}$ is any inclusion minimal tree in $H$ rooted at $r_{i}$ that contains the set $T_{i}$ of all the terminals in $\bar{T}-T_{1} \cup \cdots \cup T_{i-1}$ that are reachable in $H$ from $r_{i}$. By the construction, and since every path in $\overline{\mathcal{P}}$ collides with $\bar{P}$ and no edge leave the terminals, it is clear that the three properties given in the lemma hold. We explain why the trees $J_{1}, \ldots, J_{d}$ are pairwise edge disjoint. Otherwise, there are $1 \leq m<i \leq d$ so that $J_{m}$ and $J_{i}$ have an edge $u v$ in common. By the minimality of $J_{i}$, there is a terminal $t \in \bar{T}_{i}$ reachable from $v$ in $J_{i}$ (possibly $v=t$ ). But then $t$ is also reachable from $r_{m}$, hence, by the construction, $t$ should have appeared in $J_{m}$ and not in $J_{i}$, contradiction.

Using Lemma 4.3, we show that the metric completion of $H$ contains a low density junction startree as a subgraph. For a subgraph $J$ of $H$ let $k(J)=|V(J) \cap \bar{T}|$ denote the number of terminals from $\bar{T}$ in $J$.

Corollary 4.4 There exists a junction star-tree $J$ in the metric completion of $H$, such that (3) holds.
Proof: Let $J_{1}, \ldots, J_{d}$ be the decomposition of $H$ into trees as in Lemma 4.3. We will extend these rooted trees to junction star-trees by adding for every st path in $\mathcal{P}$ an edge $s r_{i}$ from $s$ to the root $r_{i}$ of the tree $J_{i}$ which includes $t$ (see Fig. $1(\mathrm{~b})$, if $s=r_{i}$ we need not add this edge). The cost of each new edge is at most $2 c(H) / g$, since it shortcuts a path that is obtained by joining two subpaths of truncated paths (recall that each truncated path has cost less than $c(H) / g)$. Let $J_{1}^{+}, \ldots, J_{d}^{+}$denote the resulting junction star-trees. Every junction star-tree connects all its sources to the corresponding terminals, and therefore $\sum_{i=1}^{d} k\left(J_{i}^{+}\right)=\ell$. On the other hand we can bound the sum of the costs of the junction star-trees as follows:

$$
\sum_{i=1}^{d} c\left(J_{i}^{+}\right)<\sum_{i=1}^{d} c\left(J_{i}\right)+\ell \cdot \frac{2 c(H)}{g} \leq c(H)+\ell \cdot \frac{2 c(H)}{g}
$$

The last inequality holds because $J_{1}, \ldots, J_{d}$ are subgraphs of $H$ that are pairwise edge disjoint. Using an averaging argument we get that there must be a junction star-tree $J=J_{i}^{+}$whose density is bounded by:

$$
\frac{c(J)}{k(J)} \leq \frac{c(H)+\ell \cdot 2 c(H) / g}{\ell}=\frac{c(H)}{\ell}+\frac{2 c(H)}{g} \leq c(H) \cdot\left(\frac{g}{k}+\frac{2}{g}\right)
$$

Where the last inequality holds because $\ell \geq k / g$.

### 4.2 The algorithm

Given a $k$-DSF instance assume that Reduction 2 and 3 are implemented.
Lemma 4.5 For any $k$-DSF instance (after applying Reductions 2, 3), there exists a junction star-tree $J$ so that $c(J) /|\mathcal{D}(J)| \leq \mathrm{opt} \cdot \sqrt{8 / k}$.

Proof: Let $g=\sqrt{2 k}$. If $c(P) \leq c(H) / g$ for some $s t$-path $P$ with $(s, t) \in \mathcal{D}$, then $P$ is the required junction-star tree. Otherwise from Theorem 4.1, by choosing $H$, as an optimal solution of the $k$-DSF instance (after applying Reductions 2, 3), we get that $H$ 's metric completion contains a junction star-tree $J$ of density $c(J) /|\mathcal{D}(J)| \leq \sqrt{8 / k} \cdot c(H)$.

Example: This example shows that the bound in Lemma 4.5 is tight up to a constant factor. Consider the graph in Fig. 2, where $\mathcal{D}=\left\{\left(s_{i}, t_{j}\right): 1 \leq i, j \leq k\right\}$. Here $k=q^{2}$, and the lowest possible density of a junction star-tree is $(q+1) / q>1$, while the density of the optimal solution (which is the entire graph) is $2 q / q^{2}=2 / q$.

Lemma 4.6 Suppose that there exists an algorithm that given an instance of $k$-DSF finds an edge set $J$ of density $\sigma \leq \mathrm{opt} \cdot \rho(k) / k$ and the set $\mathcal{D}(J)$ of demand pairs that $J$ connects in $T^{\prime}(n, k)$ time. Then the $\rho(x)$-Greedy Algorithm for $k$-DSF can be implemented in $O\left(k T^{\prime}(n, k)\right)$ time.

Proof: We need to show how to find a low density edge set $J$ for every instance $G, c, \mathcal{D}$ of $k$-DSF and every partial cover $F$. With that aim in mind, set $\mathcal{D}^{\prime} \leftarrow \mathcal{D}-\mathcal{D}(F)$ to get an instance $G, c, \mathcal{D}^{\prime}$ of $(k-|\mathcal{D}(F)|)$-DSF. Then use the given algorithm for finding an edge set $J$ of density at most opt $^{\prime} \cdot \rho(k-|\mathcal{D}(F)|) /(k-|\mathcal{D}(F)|)=$ opt $^{\prime} \cdot \rho(\nu(F)) / \nu(F) \leq$ opt $\cdot \rho(\nu(F)) / \nu(F)$, where opt and opt ${ }^{\prime}$ denote the optimum solution values of the instances $G, c, \mathcal{D}$ and $G, c, \mathcal{D}^{\prime}$, respectively. The number of

Figure 2: An example showing that the bound in Lemma 4.5 is tight.
iterations is at most $k$, since in each iteration at least one more demand pair is satisfied. Hence the time complexity is $O\left(k T^{\prime}(n, k)\right)$.

If we could find a low-density junction star-tree as in Lemma 4.5 in polynomial time, then we would obtain an $O(\sqrt{k})$-approximation algorithm for $k$-DSF, by Theorem 2.1 and Lemma 4.6. We will show how to find a junction star-tree of approximately optimal density using any approximation algorithm for $k$-DST; in particular, we can use the algorithm of [2].

Corollary 4.7 If $k$-DST admits an $\alpha$-approximation in $T(n, k)$ time then there exists an algorithm that given an instance of $k$-DSF finds a junction star-tree $J$ satisfying $\sigma(J) \leq \mathrm{opt} \cdot \alpha \cdot \sqrt{8 k} / k$ and $\mathcal{D}(J)$ in $O(n k T(2 n+k, k))$ time.

Proof: We may assume that we know the root $r$ of some optimal density junction star-tree, as we may try every $r \in V$. For every demand pair $(s, t) \in D$, add a new node $t^{\prime}$ and the edge $t t^{\prime}$ of cost $c(s r)$ (if $s=r$ let the cost of the edge be 0 ). Let $T^{\prime}$ be the set of nodes added. For every $1 \leq k^{\prime} \leq k$ apply the $\alpha$-approximation algorithm on the obtained instance of $k^{\prime}$-DST with root $r$ and terminal set $T^{\prime}$. From the solutions computed, output the one $J^{\prime}$ with minimum density. The junction star-tree $J$ is obtained from $J^{\prime}$ by replacing every terminal $t^{\prime}$ of $J^{\prime}$ by the corresponding edge $s r$. It is easy to see that $J^{\prime}$ is as required, and that it is possible to calculate $\mathcal{D}\left(J^{\prime}\right)$ without increasing the time complexity. The graph on which we call the algorithm for $k^{\prime}$-DST has $n+|T|+|S|+k$ nodes due to Reduction 2 and the addition of the nodes of $T^{\prime}$. However, $|S|$ of these nodes are sources (into which no edge enters) and can be removed before the algorithm for $k^{\prime}$-DST is called. The time complexity follows.

Combining Corollary 4.7 with the result of [2], Theorem 2.1, and Lemma 4.6, gives Theorem 1.2.
Remark: When using the algorithm of [2] for $k$-DST, the time complexity in Corollary 4.7 is in fact $O(n T(2 n+k, k))$, since this algorithm approximates the minimum density augmentation tree in a $k$-DST instance within the same time bound as approximating $k$-DST.

## 5 Conclusions and open problems

We presented the first sub-linear, in terms of $n$, approximation algorithm for the DSF problem. Due to a reduction from LABEL-COVER $\max ^{[7]}$, obtaining an approximation ratio better than $O(\sqrt{n})$ (namely, $O\left(n^{1 / 2-\varepsilon}\right)$ for some constant $\varepsilon>0$ ) for DSF is unlikely, as it implies improving the best ratio for LABELCOVER $_{\text {max }}$ due to Peleg [30]. Still, it is an open question whether this ratio is indeed feasible. We also presented a simple combinatorial $O\left(k^{1 / 2+\varepsilon}\right)$-approximation scheme for $k$-DSF, which matches the best known LP-based algorithm of Chekuri et al. [3] for the less general problem DSF. Our result also (almost) matches the best know ratio in terms of $k$ for the undirected version of the problem by Gupta et al. [14]. It is interesting to note that the situation is completely different in terms of $n$, as there is no known non-trivial approximation ratio for $k$-DSF in terms of $n$, while the undirected version admits an $O(\sqrt{n})$-approximation [14]. It is an open question whether the asymmetry between the parameters $n$ and $k$ can be reduced.

Almost every aspect of the more general Directed Steiner Network problem is still an open problem. No non-trivial approximation ratio is known for this problem, even for the simple case when the maximum requirement is 2 . In contrast, the Undirected Steiner Network problem was studied extensively, and admits a 2 -approximation algorithm due to Jain [19].

Note that the Directed Steiner Network problem can be trivially solved using min-cost flow techniques when there is only a single positive requirement pair. This fact can be used to achieve a $k$ approximation for the Directed Steiner Network problem, where $k$ is the number of positive requirement pairs: Simply solve independently for every positive requirement pair and combine the resulting graphs. A similar algorithm also extends to the more general problem of $k$-Directed Steiner Network, where we are only required to connect $k$ positive requirement pairs. Again, we can solve the problem separately for each positive requirement pair and then combine the $k$ cheapest resulting graphs.

We also note that on directed graphs, there is an approximation ratio preserving reduction between the edge-weighted and the node-weighted versions, but this is not so for undirected graphs. On undirected graphs, the best known ratio for the Node-Weighted Steiner Forest is $O(\log |U|)$ due to Klein and Ravi [23] and this is tight (up to a constant factor), where $U$ is the set of nodes involved in a positive requirement pair. Recently, an $r_{\text {max }} \cdot O(\ln |U|)$-approximation algorithm for the undirected Node-Weighted Steiner Network problem was presented by Nutov [29], where $r_{\max }=\max _{u, v \in V} r(u, v)$ is the largest requirement.

We believe that it should be possible to approximate the Directed Steiner Network problem to a factor of $r_{\max } \cdot \rho_{\mathrm{DSF}}$, where $\rho_{\mathrm{DSF}}$ is the approximation ratio of the DSF problem. A possible way to approach this ratio is through the Rooted Directed Steiner Network problem, a restricted version of the Directed Steiner Network problem in which the set of pairs with positive requirement is a subset of $\{s\} \times V$, for some node $s \in V$. We believe that an approximation ratio of $r_{\max } \cdot \rho_{\mathrm{DST}}$ should be feasible for this problem (where $\rho_{\mathrm{DST}}$ is the approximation ratio of the DST problem), and that the ideas presented in this paper can be used to reduce the Direct Steiner Network problem to a variant of Rooted Direct Steiner Network, in a way resembling our reduction from the DSF problem to a variant of DST.
